RETENTION OF HIGH TACTILE ACUITY THROUGHOUT THE LIFESPAN IN BLINDNESS

Abstract

Previous studies of tactile acuity on the fingertip using passive touch have demonstrated an age-related decline in spatial resolution for both sighted and blind subjects. We have re-examined this age dependence with two newly designed tactile-acuity charts requiring active exploration of the test symbols. One chart used dot patterns similar to Braille and the other used embossed Landolt rings. Groups of blind Braille readers and sighted subjects, ranging in age from 12 to 85 years, were tested in two experiments. We replicated previous findings for sighted subjects by showing an age related decrease in tactile acuity by nearly 1% per year. Surprisingly, the blind subjects retained high acuity into old age showing no age-related decline. For the blind subjects, tactile acuity did not correlate with braille reading speed, the amount of daily reading, or the age at which braille was learned. We conclude that when measured with active touch, blind subjects retain high tactile acuity into old age, unlike their aging sighted peers. We propose that blind people's use of active touch in daily activities, not specifically Braille reading, results in preservation of tactile acuity across the lifespan.

Keywords

touch; tactile perception; tactile acuity; aging; blindness; impaired vision

Introduction

Blind people rely more heavily on non-visual sensory information than sighted people. Until recently, it was widely believed that auditory and tactile detection and simple discrimination thresholds are similar in both blind and sighted subjects (see Hollins 1989 for a review).

Several recent studies, using modern psychophysical methods, have demonstrated that tactile spatial resolution is better in blind subjects than age-matched sighted subjects (Goldreich & Kanics, 2003, 2006; Stevens, Foulke & Patterson, 1996; Van Boven, Hamilton, Kauffman, Keenan, & Pascual-Leone, 2000), but see also Grant, Thiagarajah & Sathian (2000) who did not find a blind/sighted difference.

The ability to measure small group differences in tactile spatial thresholds has benefited from the realization that the traditional two-point threshold method is confounded by non-spatial intensity and other cues (Craig & Johnson, 2000). Preferred methods for measuring spatial resolution on the skin include gap detection (Stevens & Choo, 1996) and grating-orientation thresholds (Johnson & Phillips, 1981). In gap detection, an edge is pressed...
against the skin which is either solid or contains a gap. Gap width is varied to find a threshold size. Grating-orientation thresholds are measured with tactile gratings consisting of alternating grooves and ridges producing a periodic pattern. The gratings are pressed against the skin in one of two orthogonal orientations, and the groove and ridge width is varied to find the threshold for orientation discrimination. These methods assess the capacity of the skin to detect the presence and orientation of small spatial intervals. The resulting thresholds are consistent with the receptor density of the slowly-adapting type I (SA-I) mechanoreceptors on the fingertip, thought to be responsible for spatial acuity on the skin (Johnson & Hsiao, 1992).

As summarized in Table 1, recent measurements of spatial thresholds on the fingertip range from about 1.2 mm to 1.7 mm for young, normally sighted subjects. The thresholds for blind subjects are roughly 0.2 mm lower, ranging from about 1.0 to 1.5 mm, representing about 15% better tactile acuity. Undoubtedly, some of the numerical differences across studies in Table 1 are due to methodological differences. These differences also indicate the need for caution in interpreting the relationship between tactile acuity and Braille reading discussed below.

Braille is the most successful code for reading by touch. Braille is not a language like English or Spanish, but a code for representing the written form of a language with tactile symbols. Braille characters consist of combinations of six dots, placed in a matrix of two columns and three rows, termed a braille “cell” (Figure 1). The 64 possible arrangements of dots in the braille cell (including the blank cell) comprise the 64 characters of the braille code. Twenty-six of these characters represent the 26 letters of the English alphabet.

Identification of braille characters relies on the ability to discern the number and spatial arrangement of dots in the braille cell. As illustrated in Fig. 1, the critical features of the cell (the dots) are located in a matrix with a center-to-center spacing of 2.28 mm between nearest neighbors. It is reasonable to expect that a prerequisite for fluent reading would be tactile acuity adequate to resolve spatial details on this scale. The estimates of spatial tactile acuity in young sighted and blind subjects (Table 1) are roughly half the center-to-center dot spacing of 2.28 mm within the braille cell, representing a tolerance of only a factor of two for identifying Braille symbols. It is evident that recognition of characters in braille reading operates close to the tactile acuity limit.

The constraints imposed by tactile acuity may be more severe for older Braille readers because of the known age-related decline in tactile acuity (Table 1). Stevens et al. (1996) reported that both blind and sighted subjects display an age-related decline in tactile acuity for gap detection. This decline occurs at different rates all over the body, with acuity on the fingertip decreasing at a rate of about 1% per year (Stevens 1992; Stevens & Choo 1996; Stevens et al. 1996). An increase of 1% per year in the threshold spatial interval for tactile resolution would result in an 80% increase in tactile thresholds from 20 to 80 years of age. Stevens et al. (1996, Exp. 2) reported an increase in mean tactile threshold from 1.18 mm for their young blind group to 2.48 mm for their old blind group. Goldreich & Kanics (2003), using grating-orientation discrimination, also observed a decline in tactile acuity between 25 years and 75 years from 1.65 mm to 2.62 mm for their sighted subjects and from 1.49 mm to 2.01 mm for their blind subjects. In another study, Goldreich & Kanics (2006) found a similar age-related pattern using a tactile grating-detection method.

The above review reveals a problem in our understanding of the relationship between braille reading and tactile acuity. It is evident that braille characters are only slightly above the acuity limit for young blind readers and close to or beyond the acuity limit for old braille readers. If this is the case, braille reading should become progressively more difficult in old
age, and many older blind individuals should lose the sensory capacity to read braille. While it is notoriously difficult for late-blinded individuals to learn braille in old age, we are unaware of evidence that people who learn braille early in life and who retain good skin health become unable to read braille in old age. Stevens et al. (1996) considered this issue in their study of aging effects on tactile acuity in sighted and blind subjects. The correlations among braille reading speed, age and tactile acuity among their blind subjects were surprisingly weak or absent, depending on the conditions. They were puzzled by the lack of a more robust relationship between age and braille reading performance, and recommended the development of a tactile acuity chart, similar to the Snellen letter chart for visual acuity, to assess the adequacy of spatial resolution for braille reading.

In two experiments, we measured tactile acuity for blind and sighted subjects on two newly designed tactile-acuity charts. One of the charts used braille-like symbols composed of dot patterns. Using this chart, we found the previously observed decline in tactile acuity with age among sighted subjects. Surprisingly, the results revealed retention of high tactile acuity in old age among Braille readers. To determine whether this unexpected result was specific to the highly familiar and linguistically-laden attributes of the braille test symbols, we designed a second chart composed of symbols (Landolt rings) likely to be less familiar and less linguistically salient to braille readers. Once again, the results revealed retention of high tactile acuity in old age among the braille readers. Our surprising results conflict with the observed age-related decline in tactile acuity among blind subjects (Goldreich & Kanics, 2003, 2006; Stevens et al., 1996), but may help to explain why many blind people continue to read braille successfully into old age.

Experiment 1: Tactile Acuity as a Function of Age Using the Dot Chart

We investigated the relationship between tactile acuity and age in blind braille-readers and sighted subjects using a newly designed chart composed of symbols similar to characters used in braille reading.

Methods

Subjects—Subject characteristics are summarized in Table 2.

Forty-nine blind braille readers (age range 18–74) and 83 sighted non-braille readers (age range 12–82) participated in the study. All subjects reported having normal healthy hands. Of the 49 braille readers, 13 had some level of light perception, 33 had no residual vision, and 3 had low vision sufficient to read highly magnified print. All subjects gave informed consent, and the study protocol was approved by the University of Minnesota's Institutional Review Board.

Subjects were allowed to choose their preferred hand for testing. Sighted subjects chose their dominant hand. Blind subjects chose their preferred hand for Braille reading, which was not always the dominant hand by other tests.

The blind subjects completed a questionnaire concerning the age of onset of vision impairment, the age at which braille instruction began, and amount of daily braille reading.

---

\(^a\)One of the leading causes of visual impairment is diabetic retinopathy. Diabetes can often be accompanied by peripheral nerve damage (neuropathy) which can affect the fingers and other extremities. Neuropathy in the fingers reduces spatial tactile acuity. People with diabetic retinopathy who experience this condition may be unable to read Braille.

\(^b\)Only subjects who have never: 1) experienced tingling feeling in their hands and fingers; 2) had calluses due to instrument playing (e.g., guitar or violin); 3) had diabetes were recruited in this study.

\(^c\)For simplicity, we will sometimes refer to this group of 49 subjects as the “blind subjects.”
The blind subjects were also given a test of braille reading speed, using the MNREAD test, as part of a parallel study of reading speed (Legge, Madison & Mansfield, 1999).

All but seven blind subjects learned braille before 15 years; average age of first exposure was 9.5 (standard deviation 8.8 years). The average braille reading speed was 114 words per minute (range 14–228).

**Dot Chart for Measuring Tactile Acuity**—The dot charts were made on a carbon-plastic sheet. Two versions of the chart with different random sequences of test symbols were constructed (Figure 2a). The test symbols were four 3-dot patterns that correspond to four braille letters (d, f, h, and j) matched for legibility (Nolan & Kederis, 1969). The four characters all use three of the top four dots in the braille cell, and differed only in the spatial location of the missing fourth dot.

Each chart had nine lines of eight characters: dot separations decreased by 0.1 log unit (~26%) per line. The dot spacing on the 6th line, labeled 0.0 (Figure 2a) corresponded to standard braille characters, i.e., center-to-center spacing between nearest neighbor dots of 2.28 mm. Logarithmic spacing with step size of 0.1 log units follows the common design principle for modern logMAR letter acuity charts (cf., Ferris, Kassoff, Bresnick & Bailey, 1982). Labeling standard braille as the reference line at 0.0 log units is analogous to the common practice of labeling the line with Snellen 20/20 letters (subtending 5 min-arc) as the 0.0 log unit line on visual letter-acuity charts.

Dot amplitude and shape remained constant on all lines of the chart. A consequence of retaining invariant dot size was that lines with dot spacing less than −0.3 log units (with center-to-center dot separation of 1.14 mm) had overlapping dots which compromised character shape. As a result, the last line on the chart was at −0.3 log units.

Tests were scored on a logarithmic scale following standard methods for scoring visual acuity on a letter by letter basis (Ferris et al., 1982). Each line was worth 0.1 log unit, and each symbol 1/8 of one line or 0.0125 log units. Beginning with a perfect starting score of −0.3 representing perfect performance on all lines of the chart, 0.0125 was added for each missed or inaccurately recognized symbol–Score = −0.3 +(# of errors × 0.0125). For example, a subject who missed all eight symbols on the −0.3 log unit line but recognized all other symbols correctly would have an acuity score of −0.3 + 8 * .0125 = −0.2 log units.

**Procedure**—The chart was placed flat on the table in front of the subject. The subject reached beneath an occluding black felt cloth, supported by a frame, which blocked the view of the hands and the chart for the sighted subjects.

Blind subjects read through the test lines and reported aloud the corresponding braille letters (d, f, h, or j). Sighted subjects were given the option to report the location of the missing dot (e.g., “lower left” corresponding to the braille symbol d) or used a legend depicting the dot patterns with corresponding braille letter to match their tactile input.

The test was not timed, and accuracy was stressed over speed.

Following testing on the index finger, some of the subjects (21 blind and 23 sighted) were then tested on their ring finger (the finger next to the little finger) on the same hand. Subjects were urged to only use the ring finger and were closely monitored by the experimenter.

For both the blind and sighted groups, index and ring finger data sets were resampled one thousand times with replacement, using a bootstrap method developed by Efron &
Tibshirani (1993). Tactile acuities measured in index and ring finger were resampled 1000 times. Each resampled data set was then analyzed by Jacknife resampling techniques in Matlab (version 7 with the Statistics Toolbox) to estimate the regression statistics and correct for any bias. Each resampling produced a regression line for tactile acuity vs. age, and the cluster of regression lines for a group and finger provided a measure of variability. Confidence intervals (95%) were calculated and displayed in figures 3a and 3b to show the dispersion of the resampled regression lines.

Results

Figure 3a shows tactile acuities for 49 blind subjects and 83 sighted subjects as a function of age, measured with the dot chart. Best-fitting regression lines are shown for the two groups - dark for blind and dashed for sighted. The gray bands show 95% confidence intervals - dark gray for blind, and light gray for sighted. The left vertical scale represents the center-to-center spacing between nearest dots on a log scale, with the spacing for the standard braille cell (2.28 mm) assigned the value 0.0 log units. On this scale, larger values represent larger gap size, i.e., poorer acuity. Values larger than 0.0 represent symbols at the acuity limit that are larger than standard braille characters. The right vertical scale shows corresponding dot spacing in mm.

The rising regression line for the sighted subjects represents a progressive decrease in tactile acuity (increase in dot spacing at the acuity limit) with age. The slope is .0037 log units per year (linear regression model, p<0.001). This slope is equivalent to a change by 0.86% per year, close to the approximate value of 1% decline per year in tactile acuity on the fingertip observed by Stevens & Patterson (1995). For sighted subjects, the change from a tactile acuity of −.20 log units at 20 years to +0.03 log units at 80 years corresponds to an increase in the threshold dot spacing from 1.44 mm to 2.44 mm.

Surprisingly, braille readers exhibited no decrease in acuity with age (linear regression model, p=0.77). The mean acuity across all 49 subjects was −.27 log units, corresponding to a threshold dot spacing of 1.22 mm. The tactile acuities of the braille reading group were better than the sighted group at all ages. At age 20 the difference was 0.08 log units, which corresponds to about a 20% difference in dot spacing, and at age 80 the difference was 0.30 log units, corresponding to a 100% difference in dot spacing. The separation between the data for the sighted and blind subjects is clear; the 95% confidence limits on the regression lines do not overlap above 20 years of age.

The narrow confidence limits on the data for the blind subjects may reveal a floor effect due to the design of the chart. As described in the Methods, we could not include lines smaller than −0.3 log units without overlap of the dots which would destroy the character shape. Seven of the blind subjects were correct on all eight characters on the −.3 log units line. Across all 49 blind subjects, performance on the −.3 line was 75.3% correct, compared with a chance accuracy of 25% correct. We will return to the impact of this floor effect in the Discussion of Experiment 1 below.

For the blind subjects, the hand used, year braille was learned, years reading, years of blindness, braille reading speed, status of residual vision, gender, and hours of reading per week were not significant in predicting tactile acuity (Spearman's rho, p>0.06). For the sighted subjects, gender did not correlate with acuity (p=0.70), age was the major predictor for acuity (r_s=0.62 p<0.001).

Figure 3b shows tactile acuities of the ipsilateral ring finger, generally not used in braille reading. The age-related pattern was similar to index finger acuities, with the sighted group decreasing about 1% per year, and the blind group maintaining a high acuity across age.
Once again, the separation between blind and sighted data is clear, with the 95% confidence intervals on the regression lines being non-overlapping above age 25. For the ring finger, the variability in the blind group is greater than for the index finger, and there is less evidence for a floor effect; none of the blind subjects had perfect performance on the −0.3 line and the overall performance level was 62.5% for the blind group on this line.

Ring-finger acuities were only slightly poorer than index-finger acuities. Using the regression lines in Figures 3a and 3b to compare values at 20 years, the acuities for the sighted subjects were 1.46 mm (index) and 1.56 mm (ring), and for the blind subjects 1.21 (index) and 1.26 mm (ring). Vega-Bermudez & Johnson (2001) found a larger difference in acuities for the ring and index fingers for their group of 8 sighted subjects (males ranging in age from 22 to 57 years). Averaged across hands, the 71% correct grating orientation thresholds were 1.24 mm for index and 1.65 mm for ring finger.

Discussion

Our findings on tactile acuity are consistent with other recent findings in two ways, but have one important difference.

Consistent with recent findings (Dinse et al., 2006; Goldreich & Kanics, 2003, 2006; Stevens, 1992; Stevens et al., 2003; Stevens & Choo, 1996; Stevens & Patterson, 1995; Vega-Bermudez & Johnson, 2004), we found an age-related decline in tactile acuity on the fingertip for our normally sighted subjects. Our method for measuring tactile acuity was different from the prior studies. We used a tactile-acuity chart, modeled on the design of visual-acuity letter charts. The test involved identification of braille-like symbols and permitted the subjects to actively scan the symbols without a time limit. In contrast, the other studies used passive presentation of stimuli for fixed brief periods, and two-alternative forced choice discrimination between the presence or absence of a gap, the orientation of a tactile grating, or one vs. two points. Despite these methodological differences, there is good quantitative agreement between our results for sighted subjects and those of the other studies both in terms of the mean threshold size (1.72 mm in our study vs. 1.21 to 3.5 mm in previous studies) and the growth of threshold size with age (0.86% increase per year in our study vs. 1% change increase in Stevens and colleagues’ studies).

Also consistent with recent findings (Goldreich & Kanics, 2003; Stevens et al., 1996; Van Boven et al., 2000), we found that blind subjects have better tactile acuity than age-matched sighted subjects. The mean tactile acuity for our 49 blind subjects was −.27 log units compared with −0.12 log units for our 83 sighted subjects. This corresponds to a mean difference in threshold dot separation of 0.50 mm, compared to differences ranging from about 0.16 to 0.61 mm for the three cited studies (See Table 1).

The important difference between our results and those of other recent studies is the retention of high tactile acuity across the lifespan for our blind subjects. We did not observe the age-related decline in tactile acuity for blind subjects reported by Stevens et al. (1996) and Goldreich & Kanics (2003, 2006). What might account for this surprising retention of tactile acuity by our blind subjects and what are the implications? Before considering the implications, we describe Experiment 2 in which we considered two possible explanations related to the design of the tactile-acuity chart used in Experiment 1.

Experiment 2: Comparing Tactile Acuity with the Ring chart and the Dot Chart

A floor effect in Experiment 1 might have hidden an age-related decline in tactile acuity among our blind subjects. Most of our blind subjects could identify characters on or close to
the bottom line (~0.3 log unit) on the dot chart. As described in Experiment 1 Methods, the design did not permit lines with smaller dot spacing. It is plausible that young blind subjects might have demonstrated even better acuity if not for this floor effect, and that an age-related difference between young and old blind subjects might have emerged. We addressed the floor effect in the design of a second type of tactile acuity chart, the Ring chart shown in Fig. 2b. This chart was capable of revealing finer spatial resolution than the dot chart.

It is also possible that the linguistic properties of the dot chart provide some unique advantage to braille readers that accounts for retention of acuity across age. Perhaps their familiarity with the braille-like symbols supports performance that is specific to acuity measurements on this chart. There are two reasons to doubt this. First, if linguistic familiarity heightens acuity, we might expect to find unique characteristics of visual acuity on letter charts which do not generalize to other measures of visual acuity such as Landolt C acuity. But it is well known that both these types of acuity show similar dependence on most stimulus and subject variables. Second, while the symbols on the 0.0 log unit line of the dot chart are standard braille letters and were certainly highly familiar to our braille readers, the other symbols on the chart were not nearly so familiar. Almost all braille materials use a single size, the standard braille dimensions shown in Figure 1. Braille readers rarely encounter text in non-standard braille sizes.

We conducted tactile acuity measurements on blind and sighted subjects on both the Dot chart and a second type of acuity chart, the Ring chart (Fig. 2b). We used this comparison to assess the floor effect and possible linguistic salience of the dot chart for braille readers, and to attempt to generalize the results from Experiment 1 to a second set of test symbols. Identification of the orientation of Landolt C’s is often considered the gold standard for visual-acuity testing (National Research Council, 1980). The symbols are low in linguistic meaning and likely to be of roughly equal salience for blind and sighted subjects. For these reasons, we designed the Ring chart for testing in Experiment 2.

Methods

Subjects—22 blind braille readers were divided into a young group of 10 (mean age 31.2 yr) and an older group of 12 (mean age 66.5 yr). 19 normally sighted subjects were divided into a younger group of 10 (mean age 29.3 yr) and an older group of 9 (mean age 71.9 yr). Table 3 summarizes the characteristics of the four groups. All subjects gave informed consent, and the study protocol was approved by the University of Minnesota’s Institutional Review Board.

Ring Chart for Measuring Tactile Acuity—The Ring chart was made out of machinable wax with a computer-controlled 3D router (ShopBot CNC Router). The basic symbol of the Ring chart is the Landolt C (Windows TrueType Sloan font), presented in .4 mm relief with the gap oriented in one of four directions: up, down, left or right (see Figure 2b). The chart consists of eleven rows of eight pseudo-randomly oriented C’s per row. Sizes of the Cs decrease as rows progress toward the bottom of the chart in 0.1 log units. The sizes of the Cs change in proportion to the size of the gap in each row. The 0.0 line on the Ring chart contains C’s with gaps of 2.40 mm, nearly matched in size with the dot spacing on the dot chart (2.28 mm). This matching allows for plausible comparisons between numerical values of acuity measured on the two charts. The chart was designed to have three rows larger than this reference line extending to +0.3 log units (4.8 mm gap size), and seven

---

Some of our braille readers were initially confused by the identity of the “jumbo” braille symbols on the upper lines of the dot chart. When first introduced to the chart, a few of them confused the “f” symbol with “m” and the “h” with “u”. “m” has 3 dots in the same general configuration as “f” except that the lower dot is in the bottom location of the braille cell rather than the middle location. “u” is similar to “h” except that the lower two dots are in the bottom two locations of the braille cell.
smaller rows extending to −0.7 log units. Subsequent to manufacture of this custom chart, we directly measured the gap sizes of all symbols with a 10X reticle. We discovered two manufacturing defects at the small end of the chart. First, row −0.6 duplicated row −0.5 in gap size, and row −0.7 had the gap size we expected for row −0.6. As a result, the true range of the chart was from +0.3 log units (4.8 mm gap size) to −0.6 log units (0.55 mm gap size). Second, we discovered that at some point during testing, two of the Cs on the bottom line of the chart were damaged such that their gaps were enlarged. Accordingly, for scoring of the final line of the chart we included only the six intact symbols. We took both of these defects into account in the calculation of acuity on the Ring chart.

The design of the Ring chart differs in three important ways from the dot chart. First, the ring and gap stimuli on the Ring chart are uniformly scalable, whereas only the distance between dots of constant size were scalable in the dot chart. Second, smaller stimuli are included on the Ring chart (−0.6 log units compared with −0.3 log units for the dot chart), reducing the likelihood of a floor effect on acuity. Third, the ring stimuli on the Ring chart are expected to have minimal and roughly equivalent linguistic salience for blind and sighted subjects.

The same scoring method was used for the Ring chart as for the dot chart, except that errors were computed relative to the −0.6 log unit line, and corrections were made for the manufacturing defects discussed above: Score = −0.6 +(# of errors × 0.0125).

Procedure—For each subject, tactile acuity was measured four times on the dot chart and four times on the Ring chart. Variation in the sequence of symbols was accomplished by presenting the chart in four orientations in the four tests—normal upright orientation (with the largest symbols at the top and the smallest symbols on the bottom), 90° (with the largest symbols in the left column), 180° (with the largest symbols on the bottom) and 270° (largest symbols in the right column). In all cases, the subject read the row (or column) containing the largest symbols first, and proceeded line by line to the smallest symbols. All four measurements were completed on one chart before testing on the second chart began. The order of chart presentation (dot or Ring) alternated across subjects.

All testing was conducted on the subjects’ preferred index finger, with no testing on the ring finger. For the Ring chart, all subjects indicated the location of the gap for each symbol—top, bottom, left or right. Otherwise, the general features of testing were like those described for the dot chart in Experiment 1.

Results

The distributions of tactile acuities among the 4 groups (blind vs. sighted subjects and young vs. old subjects) deviated significantly from normal distributions with skewing in the direction of poorer acuity (Kolmogorov-Smirnov goodness of fit test, p<.05). Friedman analysis of variance (ANOVA) on the acuity values determined that neither chart orientation nor repeated measures were significant determinants of acuity for either the dot ($\chi^2=6.7$, df=3, p=0.08) or Ring chart ($\chi^2=0.64$, df=3, p=0.89). Accordingly, the acuity values for the four orientations were averaged for each subject and each chart for use in subsequent analyses. Descriptive statistics for the four subject groups are reported as medians and interquartile ranges. For statistical analyses, the subjects’ acuity values were ranked (ties averaged) and analyzed by a mixed-design ANOVA to investigate the difference in tactile acuities for each group (Conover & Iman, 1981).

Figure 4 summarizes acuities of the four groups (blind and sighted, young and old) on the dot chart (panel A) and the Ring chart (panel B).
A 3-way ANOVA was performed on the ranked values of tactile acuity with type of chart (dot and C) as a within-subject variable, and vision status (blind and sighted groups), and age (young and old groups) as between-subject variables. There was a significant main effect of vision status ($F(1,74) = 67.7, p < .001$, effect size $= 0.47$) with the blind subjects performing better than the sighted subjects on both the dot chart (by a median of 0.17 log units) and Ring chart (by 0.09 log units). There was a significant main effect of chart type ($F(1,74) = 155.6, p < .001$, effect size $= 0.68$), with Ring chart acuity better than dot chart acuity by a median of 0.125 log units. There was a significant main effect of age group ($F(1,74) = 26.4, p < .001$, effect size $= 0.26$) with the acuity of the younger subjects better than the older subjects by a median of 0.028 log units.

There was a significant interaction between age and vision status ($F(1,74) = 15.8, p<.001$, effect size $= 0.18$) reflecting a stronger effect of age on acuity for the sighted subjects than the blind subjects. The age-by-vision status interaction holds for both the dot chart and the Ring chart. Neither the age-by-chart ($p=0.13$) nor vision status-by-chart interactions ($p=0.21$) were statistically significant.

The 3-way interaction between chart type, age and vision status was statistically significant ($F(1,74)=4.31, p=0.04$, effect size $= 0.06$) indicating that the age-by-vision interaction was slightly stronger for the dot chart than for the Ring chart.

**Performance on the Dot Chart**—Old sighted subjects had significantly worse tactile acuity than young sighted subjects by a median of 0.19 log units ($p=0.001$). In contrast, there was no significant difference between the young (median of $-0.28$ log unit) and old blind groups (median of $-0.27$ log unit, $p=0.23$). The tactile acuity achieved by our blind subjects in Expt 2 was very similar to that obtained in Expt 1 ($-0.27$ log units).

Figure 5a plots acuity vs. age for the dot chart, analogous to Figure 3a in Exp. 1. Regression lines have been fit to the data for blind and sighted subjects. The pattern of results is very similar to Exp. 1. For the sighted subjects, there was a significant correlation between acuity and age ($p<0.001$). The regression line has a slope of 0.005 log units per year, equivalent to an increase of 1.15 percent per year in threshold dot spacing. This is similar to the value of .86 percent observed in Exp. 1. For the blind subjects, there was a weak correlation between age and tactile acuity ($r_s=0.42$) bordering on statistical significance ($p=0.05$). But, for this group, the growth in the tactile threshold was slight, 0.12 percent per year (the slope of the regression line was 0.0005 log units per year).

**Performance on the Ring Chart**—One goal in designing the Ring chart was to reduce or eliminate the floor effect observed with the dot chart. The symbols on the Ring chart decreased to a gap size a factor of 2 smaller than the dot spacing on the lowest line of the dot chart (~0.6 log units on the Ring chart compared with −0.3 log units on the dot chart.) If the floor effect were entirely removed, average performance should drop to the chance level of 25% correct on the bottom line of the Ring chart. Average performance across all our subjects was 7.7% on the bottom line of the Ring chart, and no subject scored better than 50% correct (3 out of 6) on this line. Moreover, variability across subjects was higher on the Ring chart (Fig. 5) as expected if there were no floor effect. We conclude that the design of the Ring chart has been successful in eliminating the floor effect found with the dot chart.

---

5This level of performance was significantly below the chance level of 25%. Some of the subjects declined to guess the orientation of the C's on the bottom line of the chart and were counted wrong for these symbols, thereby missing the opportunity for correct responses by chance.
Figure 6 plots acuity on the Ring chart vs. Dot chart for the blind and sighted groups. Regression lines have been fit to the data for blind (dark solid line) and sighted subjects (dark dotted line). For both subject groups, there was a strong and positive correlation between acuity measured by Ring and Dot charts (blind group: $r=0.85$, $p<0.001$; sighted group: $r=0.82$, $p<0.001$). These strong correlations imply that the two charts were measuring the same aspect of cutaneous spatial resolution.

Overall, acuities were better on the ring chart than on the dot chart. We will consider reasons for this difference in the Discussion subsection.

Similar to the results with the dot chart, old sighted subjects had significantly worse tactile acuity than young sighted subjects by a median of 0.125 log units ($p<0.001$). In contrast, there was no significant difference between the young (median of $-0.45$ log unit) and old blind groups (median of $-0.44$ log unit, $p=0.97$).

Figure 5b plots acuity on the Ring chart vs. age for the two groups, analogous to Figure 5a for the dot chart. Regression lines have been fit to the data for blind and sighted subjects. For the sighted subjects, there was a significant correlation between acuity and age, and the regression line has a slope of 0.004 log units per year, equivalent to an increase of 1.0 percent per year in threshold gap size for the Landolt rings, similar to the slope on the dot chart.

A major goal of Exp. 2 was to determine if retention of tactile acuity into old age would be observed for blind subjects on a test not involving braille-like symbols. Consistent with the results on the dot chart, the blind subjects exhibited no significant effect of age on tactile acuity measured with the Ring chart.

**Relationship Between Tactile Acuity and Braille Reading Speed**—The Braille reading speeds of the 22 blind subjects were measured with the Braille version of the MNREAD test (Legge, Madison & Mansfield, 1999). Their reading speeds ranged from 36 to 167 words/minute with a mean of 109 words/minute. Reading speeds for the two groups —(young, $111 \pm 26.2$ wpm; old, $108 \pm 28.8$ wpm) -- were not significantly different ($t=0.25$, df=20, $p=0.80$).

Neither braille reading speed nor tactile acuity (measured with dot or Ring chart) differed significantly between the young and old blind groups. There was no significant correlation between Braille reading speed and tactile acuity ($p>0.70$). Years of reading braille (from 16 to 75) did not correlate significantly with braille reading speed ($p=0.83$). There was a significant positive correlation between years of Braille reading and tactile acuity for the dot chart ($r_s=0.48$, $p=0.04$) but no significant correlation for the Ring chart ($r_s=0.28$, $p=0.22$).

**Discussion**

The main finding from Experiment 2 was that the surprising retention of tactile acuity in old age by blind subjects generalized from acuity measured with braille-like symbols to acuity measured with Landolt rings. Experiment 2 also showed that the lack of an age-related

---

Scoring of reading speed on the visual form of the MNREAD test takes into account that every sentence has exactly 60 characters, corresponding to 10 standard-length words, where one standard-length word is equal to six characters. This character-based metric is hard to implement for the Braille version of MNREAD sentences because Braille contractions introduce variability in the number of characters per MNREAD sentence. As described in Appendix 2 of Legge, Madison & Mansfield (1999), we have altered the scoring of the braille version of the test to take into account the number of actual words in the MNREAD sentences. Because the average MNREAD sentence has 11.9 actual words compared with 10 standard-length words, the Braille reading speeds are 19% higher than would be computed using the standard-length word metric.
decline for blind subjects observed in Experiment 1 was not due to a floor effect introduced by the design of the dot chart.

Experiment 2 also confirmed again the age-related decline in tactile acuity for sighted subjects, and the superiority of tactile acuity on the fingertip for blind subjects over agematched sighted subjects.

We did not find any association between braille reading speed and tactile acuity for our blind subjects, confirming similar observations by Stevens et al. (1996). There are two reasons why this finding may not be surprising. First, our blind subjects did not exhibit an age-related loss in tactile acuity which might have potentially resulted in an age-related loss in braille reading speed. Second, by analogy to visual reading, it may be the case that once a sufficient acuity reserve is achieved, reading speed becomes independent of acuity. In visual reading, “acuity reserve” refers to the separation in size between acuity letters and text letters. For normally sighted subjects, reading speed becomes independent of angular print size when text letters are two to three times larger than the acuity letter size (For a review, See Legge, 2007, Ch. 3). For braille readers with adequate tactile acuity, the wide range of reading speeds are probably due to differences in non-sensory manual scanning strategies and cognitive or linguistic capabilities (Millar, 1997).

Before turning to the general discussion, we comment on the acuity differences between the two charts. Acuities measured on the Ring chart were better than on the dot chart by a median of 0.125 log units (p<0.001). Undoubtedly, one reason for the chart difference is that elimination of the floor effect on the Ring chart allowed many subjects to achieve better acuities than could be measured on the dot chart.

In seeming contradiction to the difference we found on the two charts, it is generally understood that Braille letters are more legible than size-matched embossed Roman letters. Loomis (1981) demonstrated this difference experimentally. He explained this difference by hypothesizing that 1) tactile letter recognition includes a distal stage of low-pass spatial-frequency filtering; 2) the low-frequency content of Braille letters is more varied than the low-frequency content of Roman letters; and 3) following low-pass filtering, braille letters would therefore be more discriminable than Roman letters. Our Dot and Ring charts did not contain matched sets of Braille and Roman letters, so this analysis was not directly applicable. Nevertheless, it is interesting to consider how Loomis's proposed low-pass filtering might affect legibility of symbols on the dot and ring charts. In Figure 7, we illustrate the effects of low-pass filtering on dot and ring stimuli of different sizes, using Loomis's filter (Loomis, 1981; Loomis & Lederman, 1986). These blurred images provide a plausible rendering of the information available in the corresponding tactile stimuli and confirm the usefulness of Loomis's proposed filter. (Keep in mind that Loomis derived his proposed filter from measurements on young adults using passive touch.)

Consistent with our data, it is evident from Figure 7 that legibility survives to a nominally smaller size for the ring stimuli. Two attributes of the stimuli contribute to this difference. First, spacing for the dot stimuli is defined as center-to-center dot spacing rather than edge-to-edge dot spacing. By comparison, spacing for the ring stimuli is defined as the edge-to-edge gap width. This difference tends to penalize performance on the dot stimuli relative to the ring stimuli. Second, when the dot symbols get smaller, the spacing diminishes but not the dot size per se. For the smaller symbols (i.e. dot stimuli ≤ −0.3 log unit line), the large dots begin to overlap, contributing to reduced legibility. By comparison, the ring stimuli scale in size so that there is always an explicit gap present. The numerical differences in the acuity measurements on the two charts are undoubtedly influenced by these design factors.
For this reason, we do not believe that the between-chart acuity differences are likely to be of importance in our understanding of the underlying perceptual limitations.

**General Discussion**

In the Introduction, we summarized recent findings of tactile acuity thresholds for young and old subjects, and blind and sighted subjects (Table 1). Table 4 summarizes corresponding findings from our two experiments for tactile acuities.

The main finding of this paper is that tactile acuity on the fingertip does not exhibit an age-related decline in old age for blind braille readers whereas sighted subjects show the previously observed age-related decline. Constancy of tactile acuity across age for blind subjects was demonstrated in Experiment 1 on an acuity chart with braille-like dot patterns. Experiment 1 also demonstrated that the effect transferred to the ring finger which is not normally used for braille reading. In Experiment 2, the constancy of tactile acuity across age in blind subjects generalized to measurements of acuity with a Ring chart.

These results pose a puzzle. Why did we observe retention of tactile acuity across age with blind subjects while other investigators have observed an age-related decline (Goldreich and Kanics, 2003, 2006; Stevens et al., 1996)? We cannot be sure of the reason for the discrepancy but we now consider one likely possibility.

**Active and Passive Tactile Acuity**

Our study used active touch whereas most recent studies of tactile acuity have used passive touch with controlled contact force and stimulus duration. In their studies of the age dependence of tactile acuity in blind subjects, Stevens et al. (1996) and Goldreich and Kanics (2003) presented stimuli for controlled periods to a static (passive) fingertip. In our experiments, subjects freely and actively scanned the dot patterns and Landolt Cs in the acuity tests. Are there any reasons to believe that active and passive measurements of tactile acuity might have different properties?

Gibson (1962) used the concept of active touch to describe the exploration of felt objects, distinguishing it from passive touch. Passive touch refers to perception from cutaneous signals resulting from tactile stimulation of a passive observer. In contrast, active touch includes both the bottom-up tactile stimulation and kinesthetic signals from motor movements of the hands or fingers. Active touch also includes purposive action, i.e., what we might term today top-down or attention-driven tactile exploration. Gibson made the analogy to vision “these touching movements of the fingers are like the movements of the eyes. In fact, active touch can be termed tactile scanning, by analogy with ocular scanning.” Millar (1997) has argued for the importance of active touch in understanding braille reading. She has made the case that active touch is fundamentally “intersensory”, involving more than tactile input.

The differences in information available during active and passive finger touch can be understood by considering the following four cases, three of them “passive” and one “active”:

1. A static stimulus is presented to the static finger for a fixed duration. This is the prototypical “passive” touch used in most recent studies of tactile acuity.

2. A time-varying stimulus is presented to the static finger, also considered to be passive touch. The temporal profile of stimulation can affect tactile perception, distinct from the active or passive nature of the stimulation. For instance, Cascio and Sathian (2001) have shown that perceived roughness of gratings depends on
the temporal frequency of presentation to the passive finger. Vega-Bermudez, Johnson and Hsiao (1991) have studied the effect on tactile letter recognition of the velocity of stimulus scans across the passive fingertip (see further discussion of this study below).

3. The experimenter moves the subject’s passive finger over a 2D or 3D shape. In this case, the subject receives kinesthetic feedback from the finger movements, but does not issue the motor commands or plan the finger’s trajectory. Because the subject lacks control over the movement, this form of stimulation is also termed “passive” (Loomis & Lederman, 1984).

4. In active touch, the subject plans and executes finger movements to explore the target of interest, typically with the goal of making a judgment through active information-seeking. In this case, the subject receives tactile and kinesthetic input, and can invoke a strategy for tactile exploration suitable for the goal in question (Lederman & Klatzky, 1987). For acuity judgments, or other fine discriminations, active touch also permits the subject to bring the most sensitive portion of the finger pad in contact with the target.

Loomis & Lederman (1984) summarized findings with these distinctions in mind and found little compelling evidence for a performance advantage for active over passive touch. Grunwald (1966) compared braille reading speed when subjects moved their hands across lines of static text (active touch) and when an “endless line” of text moved past their stationary fingers (passive touch). Reading speed was slightly faster in the passive case, probably because of time saved in not needing to return the fingers to the left margin after each line was read.

But some subsequent findings have revealed performance advantages for active touch. Heller (1986) tested tactile pattern recognition for normally sighted college students. The stimuli were the 26 braille characters of the alphabet. A subject felt the character for 15 sec and then responded by matching it to a visual representation of the characters. Subjects were tested with active touch (free movement of the finger over the static character), passive touch with a static presentation of the character to the finger, and passive touch with the character moved either horizontally or vertically back and forth across the static finger. Accuracy was higher for the active condition compared with the other conditions, and higher for the horizontally and vertically moving presentations than for the static presentation.

Loomis (1985) has shown that there is an increasing advantage for active over passive touch for identification of tactile letters as the relief height decreases. For letters with the relief height of braille dots (approximately 0.4 mm), Loomis found that identification accuracy was 35% better for active compared with passive touch.

There is recent neural evidence for distinct sensory processing of active and passive touch. Krupa, Wiest, Shuler, Laubach, & Nicolelis (2004) found different patterns of response to similar whisker stimulation in rat somatosensory area S1 during active and passive tactile stimulation. The differences could not be accounted for by bottom-up effects, implying the involvement of top-down signals in the sensory processing of active touch. Ferezou, Bolea & Petersen (2006) observed different patterns of response in the barrel cortex of awake behaving mice compared with passive stimulation of the whiskers of awake mice. There is also evidence for movement-related attenuation of cutaneous inputs from human sensory evoked potentials and animal electrophysiology (Chapman, 1994). This gating behavior might be expected to yield poorer discrimination performance for active touch, but see Chapman (1994) for a review of several mitigating factors.
Vega-Bermudez, Johnson and Hsaio (1991) measured accuracy of tactile letter recognition for sighted subjects as a function of the velocity of lateral stimulus scans across a passive finger. They compared performance with this type of passive touch to performance when the subjects actively scanned the letters with their own finger movements. Accuracy was no better during the active scanning than the passive scanning. This lack of a difference, however, does not exclude the possibility that experience with active tactile scanning by blind subjects could result in modified neural representations for active touch.

To briefly digress, Vega-Bermudez et al (1991) found that the accuracy for tactile letter recognition was constant for rates of lateral scanning of stimuli across the fingertip from 20 to 40 mm/sec, but declined for a scanning rate of 80 mm per sec. Legge, Madison and Mansfield (1999) found that the median braille reading speed for a group of 44 experienced braille readers was 7.5 characters/sec, equivalent to 47.6 mm per sec (the center-to-center spacing between standard braille characters is 6.35 mm). Although perhaps a coincidence, the agreement between the median scanning rate for braille readers and the limiting scanning rate found by Vega-Bermudez et al. (1991), might indicate that a temporal processing limit places a boundary on braille reading speed--a velocity of approximately 50 mm per sec on the finger corresponding to an exposure time of 130 ms per character on the fingertip.

These considerations indicate that active touch might be qualitatively different from passive touch and might exhibit qualitative differences in the age dependence of tactile acuity or other properties. The active/passive distinction appears to be the most salient difference between our method for measuring tactile acuity and the methods used by Stevens et al. (1996) and Goldreich and Kanics (2003), and hence the most likely suspect to account for the important difference in results.

If this interpretation is correct, it remains to be determined what aspect of active touch protects tactile acuity in blind subjects from an age-related decline. One possibility pertains to the kinesthetic information. Blind subjects may learn effective motor strategies for collecting information about fine tactile features, and these strategies may offset a concomitant sensory decline. For instance, blind subjects may learn how to accumulate noisy information across repeated touches, analogous to probability summation across time in visual contrast detection (cf., Legge, 1978). A second possibility pertains to the quality of tactile input. Blind subjects may be more adept at learning to use the most sensitive portion of the finger pad for fine tactile discrimination. This could be especially helpful if the age-related decline in sensitivity across the finger is not uniform, with some small patches retaining high acuity longer than others.

**The Role of Experience**

What aspects of the lives of our blind subjects account for their advantage in tactile acuity, and the age-related retention of active tactile acuity? Is it the prolonged experience with braille reading? Probably not. From our findings and those of Stevens et al. (1996) there is little or no association between braille reading speed and tactile acuity. Similar to Goldreich & Kanics (2003, 2006), we did not find a significant correlation between the tactile acuity of our blind subjects and the age at which braille was learned, or the amount of daily or weekly reading. And we found only a weak correlation between tactile acuity and the number of years reading Braille. Moreover, Goldreich & Kanics (2003, 2006) found that even blind subjects who did not read braille had superior tactile acuity to age-matched sighted subjects.

Is the lack of a close link between tactile acuity and braille reading surprising? Proficient braille reading requires the ability to recognize braille characters. But we presume that these characters are sufficiently above the tactile acuity limit in size. Proficient braille reading also requires adoption of appropriate scanning strategies with the fingers and two hands (Millar,
1997). Undoubtedly, adoption of these strategies enhances braille reading speed, analogous to the skilled use of eye movements in visual reading, but it is not apparent that these strategies enhance tactile acuity. Appealing to analogies with print reading, for normally sighted individuals, enhanced visual acuity is not associated with age of learning to read print, number of years of reading, or the number of hours per day of reading. On the contrary, it has been argued that visual reading during the early school years contributes to the phenomenon of school myopia which, at least for distance viewing, reduces visual acuity (Wallman & Winawer, 2004).

Goldreich & Kanics (2003) favor the view that blindness per se, rather than enriched tactile experience, promotes enhanced tactile acuity. But a recent study by Ragert et al. (2004) suggests that enriched tactile experience in sighted people is associated with superior tactile acuity. Ragert et al. (2004) demonstrated that a group of young (21 to 27 yrs) sighted professional pianists had superior tactile acuity to an age-matched group of non-musicians. This difference was probably due to the enriched tactile experience of the pianists (although it is possible that the pianists became successful musicians because of pre-existing superior tactile acuity). Two recent studies show that sighted subjects with blind-folding for 5 days (Kauffman, Théoret, & Pascual-Leone, 2002) or 90 mins (Facchini & Aglioti, 2003) show reversible passive tactile acuity gains. It remains unclear whether superiority of tactile acuity in blind subjects is due to visual deprivation or enriched tactile experience or both.

It should be noted that we did not find a significant correlation between duration of blindness and tactile acuity (Exp. 1). But all our subjects had been blind for an average of 34.8 years, so there was ample opportunity for blindness-related changes in tactile acuity to occur.

What type of tactile experience, not specific to braille, could differ between blind and sighted people? Blind people rely on tactile shape or texture discrimination to make many daily decisions for which sighted people generally rely on vision, e.g., distinguishing among coins or keys, aligning the cap on a child-proof pill container, or finding clothing by fabric texture. Sighted people handle and touch all the objects in these tasks, but are rarely required to focus their attention on the tactile attributes necessary to make the discrimination. Many laboratory studies have shown that attention to stimulus attributes promotes improved perceptual discrimination as represented by psychophysical threshold performance (cf., Ahissar & Hochstein, 1993) or in the nature of the response or representation in sensory cortex (Hsiao, O'Shaunessy & Johnson, 1993; Polley, Steinberg & Merzenich, 2006). While braille reading may not press blind people to their tactile discrimination thresholds, many other daily tasks probably do. Focused attention on a myriad of such tasks over a prolonged period could result in enhanced tactile acuity, and potentially protect tactile acuity against age-related decline. In brief, the proposal here is that blind people's active touch, often compelled by necessity to operate near the threshold for detection or discrimination, contributes to both enhanced tactile acuity and protection of tactile acuity against age-related decline.

Enhanced Tactile Acuity in the Blind: Is it Central or Peripheral?

It is generally agreed that spatial tactile resolution on the fingertip and elsewhere on the body is limited by the neural innervation density and spacing of the slowly adapting type I mechanoreceptors (Craig & Lyle, 2001, 2002; Johnson & Hsiao, 1992).

What is the anatomical basis of the age-related decline in tactile acuity on the fingertip for normally sighted subjects, and the superior tactile acuity of blind subjects? It is plausible to seek explanations in terms of integrity of physiological structures at the fingertip itself. But several plausible peripheral explanations for the age-related decline have been largely
eliminated. These include physical wear and tear on the fingertip (Stevens et al., 2003), decreased cutaneous blood flow (Stevens et al., 2003), and decreased conformance (pliability) of the skin (Vega-Bermudez & Johnson, 2004). Given that these peripheral factors do not account for the age-related decline in the tactile acuity of sighted people, it does not seem plausible for them to account for the preserved active tactile acuity of the blind. Our finding that tactile acuity is preserved on the ring finger of braille readers as well as the primary reading finger (Exp. 1) also argues against an explanation specific to the mechanical properties of the fingertip.

If peripheral factors do not account for the privileged qualities of tactile acuity in blind subjects, what are the plausible central sites?

Enlarged evoked potentials from somatosensory cortex have been reported for stimulation of the Braille-reading index finger of blind subjects in comparison with the contralateral index finger (Pascual-Leone & Torres 1993). The apparent finger specificity of this effect would not account for our observation of a transfer of preserved tactile acuity to the non-reading ring finger in blind subjects (Exp. 1). Nor would it account for the lack of relationship between tactile acuity and the history or daily amount of braille reading. Other authors have proposed that the enlarged representation of the primary braille reading finger in area S1 of somatosensory cortex might be due to the development of extra connections with motor cortex associated with the sensorimotor aspects of braille reading rather than enhanced tactile perception (Goldreich & Kanics, 2003; Millar, 1997).

Evidence for activation of “visual cortex” in blind subjects by tactile stimulation (Buchel, Price, Frackowiak & Friston 1998; Burton et al., 2002; Cohen et al. 1997; Sadato et al. 1996;) raises the question of the functional significance of this cross-modal activation. Disruption of visual cortex in blind people by transcranial magnetic stimulation (TMS) impairs performance on both braille reading and tactile identification of raised Roman letters (Cohen et al., 1997). These authors proposed that recruitment of visual cortex for tactile analysis in blind subjects might account for their superior tactile perception. Subsequent studies have revealed that short-term blindfolding of normally sighted subjects (on the order of hours or days) is accompanied by increased involvement of visual areas (including primary visual cortex V1) in the neural processing of tactile stimuli (Merabet et al., 2007; Weisser, Stilla, Peltier, Hu, & Sathian, 2005). Although we do not yet have a firm link between Characteristics of Tactile processing in visual cortex of blind people and their enhanced and preserved tactile acuity, the findings do point to visual cortex as a plausible site for the extra neural resources.

**Implications for Reading Braille**

Young sighted and young blind subjects both have tactile acuities that permit identification of patterns smaller than braille letters by close to a factor of two. By analogy to visual reading, it is likely that some “acuity reserve” is necessary for good reading, although the size of the acuity reserve for braille reading is unknown. Blind braille readers retain high tactile acuity throughout their lifetime. Barring interference from health problems affecting the hands or fingers, they can expect to continue proficient braille reading into old age.

The age-related loss in tactile acuity among sighted subjects inexorably reduces the “acuity reserve” relative to standard braille characters. According to the regression line in Figure 3a, by age 74, the acuity reserve for the sighted subjects has shrunk to zero (i.e., braille letters are at the acuity limit of 0.0 log unit). By this age, the requisite acuity reserve for skilled braille reading has likely long since been depleted, threatening any possibility of learning to read Braille fluently. The majority of people in developed countries who are blind or who have severe low vision acquire their condition late in life from age-related forms of eye
disease. It is this large group of late-blind individuals who are at risk for being unable to learn braille because of their age-related loss of tactile acuity.

It remains possible that some form of tactile training might restore some of the lost acuity (cf., Dinse et al., 2006). There is evidence that blindfolding of young sighted subjects over a period of five days improved performance in tactile discrimination (Kauffman et al., 2002). It remains to be learned whether remedial training could be effective in enhancing tactile acuity in late-blinded individuals, and whether such enhancement would facilitate learning to read braille.

The blind poet Stephen Kuusisto, sensing the challenge of learning braille in midlife and the relevance of high-level processes, wrote (Kuusisto, 1999): “To learn Braille in your 40’s you must refresh the very infancy of touching and recharge your hands. Braille can’t be learned like Berlitz Spanish, you have to think with your skin.” The age-related loss in tactile letter acuity reported in this paper, and corresponding reduction in the acuity reserve, may explain why late-blinded individuals are rarely successful in learning to read braille.

Acknowledgments
We thank Merv Bergman for his help in producing the dot chart, Jim Williams for help in producing the Ring chart, Denis Pelli for supplying us with the image file of the Landolt C, Paul Beckmann for supplying the reticle, Steve Mansfield and Paul Schrater for helpful comments and assisting with data analysis. Thanks also to Michelle Wirth and Chris Beckmann for assistance with data collection, and to the many subjects who gave their time and insight to the study. A preliminary report on the results in Exp. 1 was given at the 1998 ARVO meeting (Madison & Legge, 1998). This work was supported by NIH grant EY002934 to G.E.L.

Figure 1.
Three adjacent braille cells are shown, illustrating the standard dimensions of the braille cell and the rendering of the three-letter word “dog”. The six possible dot positions in each braille cell are portrayed in outline with the actual dots shown in black. For instance, the braille character consisting of the top four dots of the cell represents the letter g. According to Nolan and Kederis (1969), individual dots have a base diameter of 1.5 mm, and a height above the page of 0.43 mm. Horizontally or vertically adjacent dots within a cell have a center-to-center separation of 2.28 mm.
Figure 2.
Illustration of the dot chart (top) used in both experiments, and Ring chart (bottom) used in Exp. 2. Both charts are composed of four symbols, arranged in rows of decreasing size in 0.1 log-unit steps (26% change in size). Line 6 of the dot chart is considered as a reference (0.0 log units) and has symbols from the standard Braille alphabet d, f, h, and j as shown beneath the chart). On this line, the center-to-center dot spacing is 2.28 mm. Line 4 on the Ring chart is the reference line (0.0 log units) and has rings with gaps of 2.4 mm, nearly matched to the dot spacing on the reference line of the dot chart. See the text for other details of chart design.
Figure 3.
Tactile acuity is plotted as a function of age for blind (diamonds) and sighted subjects (stars) in Exp. 1. Measurements were obtained with the dot chart (see Figure 2a) for the index finger (panel a) and the ring finger (panel b). Acuity values refer to the center-to-center separation of adjacent dots in log units (left scale) or in mm (right scale.) A horizontal line shows the dot separation for standard Braille symbols (0.0 log units, and 2.28 mm). Data are shown for 49 blind subjects (diamonds) and 83 sighted subjects (stars). Also shown are regression lines (least square fit - dark line for the blind subjects and dashed line for the sighted subjects) and 95% confidence intervals determined with a resampling method as
described in the Method section for blind (dark gray band) and sighted subjects (light gray band).
Figure 4.
Median tactile acuities and error bars showing one interquartile range are shown for four groups for measurements with the dot chart (panel a) and the Ring chart (panel b) in Exp. 2.
Figure 5.
Tactile acuity on the index finger is plotted as a function of age for blind and sighted subjects in Exp. 2. Measurements were obtained with the dot chart (panel a) and the Ring chart (panel b). Acuity values refer to the center-to-center separation of adjacent dots, or the size of the gap in the Landolt rings, in log units (left scale) or in mm (right scale.) Data are shown for 22 blind (diamonds) and 19 sighted (stars) subjects. Also shown are least-squares regression lines (dark for blind and dashed for sighted) and 95% confidence intervals determined with a resampling method as described in Exp. 1 (dark gray band for blind and light gray band for sighted).
Figure 6.
Tactile acuity measured on the Ring chart is plotted against the tactile acuity measured on the Dot chart for 22 blind (diamonds) and 19 sighted subjects (stars) in Exp. 2. Acuity values, in log units, refer to the size of the gap in the Landolt rings (vertical axis) and the center-to-center separation of adjacent dots in the Dot chart (horizontal axis). The gray dash line is the equality line showing what would be expected if tactile acuities measured on the two charts were the same.
Figure 7.
Low-pass-filtered (blurred) images are shown for dot symbols and Landolt C symbols for a range of sizes as indicated on the left. The filter, proposed by Loomis, had a 2D Gaussian impulse response function with full-width at half amplitude of 5.88 mm, and is thought to represent the intrinsic spatial filtering of cutaneous processing on the fingertip (Loomis, 1981; Loomis & Lederman, 1986).

aValues for Goldreich & Kanics (2003) were derived from regression lines for threshold vs. age for blind and sighted groups, with “young” values being the thresholds at 25 years and “old” values being the thresholds at 75 years. The individual data (thresholds for 50-gm contact force) were provided by Daniel Goldreich (personal communication, Dec. 13, 2007).

bStandard errors were not available for these thresholds.

Tactile acuities are shown for subjects 20 and 80 years of age, with values taken from the regression lines in Figure 3 (Exp. 1) and Figure 6 (Exp. 2). Tactile acuities are expressed in both log units and millimeters corresponding to threshold dot separation (Dot chart) and threshold gap size (Ring chart).
